ABSTRACT
An important tool to evaluate the influence of these public transit investments on transit ridership is the application of statistical models. Drawing on stop level boarding and alighting data for the Greater Orlando region, the current study estimates spatial panel models that accommodate for the impact of spatial and temporal observed and unobserved factors on transit ridership. Specifically, two spatial models: (1) Spatial Error Model and (2) Spatial Lag Model are estimated for boarding and alighting separately by employing several exogenous variables including stop level attributes, transportation and transit infrastructure variables, built environment and land use attributes, sociodemographic and socioeconomic variables in the vicinity of the stop along with spatial and spatio-temporal lagged variables. The model estimation results are further augmented by a validation exercise. These models are expected to provide feedback to agencies on the benefits of public transit investments while also providing lessons to improve the investment process.

Keywords: Ridership, Transit, Public Transport, Panel regression model, Temporal, Spatial.
1. INTRODUCTION
The over-reliance on private automobile in the US over the last few decades has resulted in various negative externalities including traffic congestion and crashes, air pollution associated environmental and health concerns, and dependence on foreign fuel (Schrank et al., 2012). There is renewed enthusiasm among policy makers and transportation professionals to counter the private automobile reliance. Several urban regions are promoting public transportation and non-motorized modes of travel through infrastructure investments such as public transit extensions, new commuter rail addition, and bicycle sharing systems (see Jaffe, 2015 and TP, 2018 for public transportation projects under construction or consideration). While non-motorized modes of transportation are beneficial in the urban core, public transit with its reach to serve populations residing throughout the urban region can enhance mobility for a large share of urban residents.

The public transit investments are critical in growing urban regions such as Orlando, Florida. In recent years, the Greater Orlando region has experienced rapid growth. In fact, according to the US Census Bureau, Orlando is the fastest growing urban region among the country’s thirty large urban regions (Brinkmann, 2016). It is reported that the majority (about 74%) of the population growth in the region is driven by domestic and international migration. The rapid increase in population elevates the stress on the existing transportation system. Thus, it is not surprising that several transportation and public transit investments are underway in the region to alleviate traffic congestion and improve mobility for Greater Orlando residents. An important tool to evaluate the influence of these public transit investments on transit ridership is the application of statistical models. Transit system managers and planners mostly rely on statistical models to identify the factors that affect ridership while also quantifying the magnitude of the impact (for example see Chakour & Eluru, 2016; Pulugurtha & Agurla, 2012). These models provide feedback to agencies on the benefits of public transit investments while also providing lessons to improve the investment process.

Orlando, a typical American city in the south, represented by urban sprawl, excessive dependence on automobile and a captive ridership, provides an ideal test bed to identify factors influencing public transit ridership. Drawing on stop level public transit boarding and alighting data for 6 four-month periods from May 2013 to April 2015, the current study estimates stop-level ridership models. Specifically, we apply a spatial panel regression model that accommodates for the influence of observed exogenous factors as well as unobserved factors. In terms of exogenous factors, we consider stop level attributes (such as headway), transportation infrastructure variables (such as secondary highway length including major and minor arterials, and major collectors; railroad length; local road length and sidewalk length), transit infrastructure variables (bus route length, presence of shelter and distance of bus stop from central business district (CBD)), land use and built environment attributes (land use mix, household density, employment density) and demographic and socioeconomic variables in the vicinity of the bus stop (income, vehicle ownership, age and gender distribution).

The repeated observation data at a stop-level offers multiple dimensions of unobserved factors including stop-level, spatial and temporal factors. For instance, it is possible that bus ridership of one bus stop is potentially influenced by the ridership of the neighbouring bus stops. It is also possible that ridership of a bus stop is influenced by the ridership levels of the previous time slots for the stop, while also being interconnected with the ridership of the neighbouring bus stops of the earlier time periods. Neglecting such spatial and temporal interconnections (if present) may result in biased estimates of the underlying ridership mechanism. To that extent, the major objective of this study is to accommodate for spatial and temporal effects (observed and
unobserved) for modeling bus stop level ridership. In our analysis, we apply a framework proposed by Elhorst (2014) to accommodate for the aforementioned observed and unobserved factors (spatial and temporal effects). Further, to accommodate for the repeated observations of ridership, we employ spatial panel model in the current study context. The panel models developed include panel spatial error and panel spatial lag formulations (see Faghih-Imani & Eluru, 2016 for a similar formulation in another context). A validation exercise is conducted to illustrate the applicability of the model framework.

The remainder of the paper is organized as follows. An overview of earlier research is described in Section 2 along with the current study section. In Section 3, the methodology has been outlined. In Section 4, the empirical analysis has been presented along with the data source, and data preparation description for modeling. The model estimation results has been presented in Section 5 along with the discussion on the model results and validation. Finally, Section 6 provides a summary of the findings and concludes the paper.

2. LITERATURE REVIEW AND CURRENT STUDY

Traditional travel demand modeling research has focused on automobile travel. Only recently studies have begun to undertake detailed analysis of transit systems and associated ridership. These studies examine transit ridership to identify the impact of socioeconomic characteristics, built environment, and transit attributes on ridership across different contexts (Chakour & Eluru, 2016). These studies broadly examine macro-level ridership (Chakraborty & Mishra, 2013; Taylor et al., 2009), study impact of financial attributes such as fare, fuel price and parking cost (Chen et al., 2011; Currie & Phung, 2007; Hickey, 2005; Lane, 2010, 2012; Mattson, 2008, Tsekeris & Voß, 2010), effect of transit attributes, transit level of service (de Ona et al., 2013; Eboli & Mazzulla) and built environment on transit ridership. For the current research effort, the last group of studies are particularly relevant. These studies can be classified by the transit mode of interest such as rail, metro and bus. As the focus of our current work is bus transit ridership, we limit our review to bus ridership studies. For studies on rail and metro, we refer the reader to (Chakour & Eluru, 2016; Rahman et al., 2017). For bus ridership studies, at the bus-stop level, the most common dependent variables of interest include daily level or time-period specific boarding and alighting variables or a sum of boarding and alighting variables. A brief review of most relevant literature follows.

Ryan and Frank (2009) highlighted the value of walkability of an area – computed based on land use mix, street patterns and density – in determining transit ridership for San Diego. Johnson (2003) studied transit boarding’s in the Twin Cities region using an ordinary least square approach. The analysis highlighted the value of vertical mixed-use and retail establishments close to the stops. The study also found that population density in the larger vicinity of the stop is more critical to ridership compared to population immediately close to the stop. Pulugurtha and Agurla (2012) applied spatial proximity and spatial weighting methods to analyze stop level ridership data from Charlotte. The models were estimated under various buffer sizes and the authors concluded that 0.25-mile buffer provided adequate model fit. Dill et al. (2013), using data from Portland, Eugene-Springfield and Jackson County, estimated separate log-linear regression models for each region and concluded that improving transit level-of-service and developing pedestrian friendly environment near the stops positively influenced ridership.

Employing a simultaneous model that accommodates for interaction between transit supply and demand in Bogotá, Estupiñán and Rodríguez (2008) concluded that promoting walking and creating barriers to car use are likely to increase ridership. Banerjee et al. (2005) examined two corridors in Los Angeles and concluded that several land use and sociodemographic variables
affected ridership on rapid bus transit systems. Tang and Thakuriah (2012), highlighted that the value of real-time bus information is slightly increasing the bus ridership in Chicago. Chakour and Eluru (2016) employed a composite maximum likelihood approach based ordered response model to accommodate for common unobserved factor influencing time-period specific boardings and alightings. The results clearly highlighted the presence of such unobserved dependencies in addition to the impact of land-use and urban form variables. More recently, using the same data as adopted in the current paper, Rahman et al. (2017) formulated a grouped ordered response model structure that allowed for correlation between daily boardings and alightings at a stop level. The study also accommodated for repeated measures of data available. The study found that transit service affected ridership significantly while the effect of land use and urban form variables was substantially different across various buffer sizes. Further, in their analysis, bus route length, sidewalk length, the presence of low-income population, the proportion of no vehicle population was likely to increase stop-level ridership.

Current Study
The review of earlier research indicates the burgeoning research in the bus transit ridership field. However, the literature is not without limitations. First, earlier work is usually based on a cross-sectional – a single time snapshot – ridership data (except for Rahman et al., 2017). Second, earlier literature on bus transit ridership has not accommodated for observed and unobserved spatial effects on ridership. Toward addressing these limitations, we formulate and estimate a spatial panel model structure that accommodates for repeated ridership data for the same stop as well as the impact of spatial and temporal observed and unobserved factors.

In our data, we have average daily boarding and alighting ridership, for weekdays only, for 6 four-month time periods between May 2013 and April 2015. Toward accommodating for spatial factors, we consider the most commonly employed spatial error and spatial lag variants employed for cross-sectional data analysis. The models are developed separately for boardings and alightings. The results from the spatial error and lag models are compared with the results from simple linear regression models to identify the improvement in model fit with accommodation of spatial unobserved effects and panel repeated measures. The model estimation process is conducted employing a host of exogenous variables generated for the study region. The estimated models are validated using a hold-out sample.

3. METHODOLOGY
In this paper, we considered boarding and alighting data for each bus stop for six time periods. The brief overview of the econometric methodology is presented in this section (see Elhorst, 2014 for complete econometric model details).

Let $q = 1, 2, ..., Q$ (in our study $Q=3,495$) be an index to represent each station (spatial unit) and $t = 1, 2, ..., T$ (in our study $T=6$) be an index for each time period. A pooled linear regression model for panel data considering spatial specific effects without considering spatial dependency can be written as:

$$ y_{qt} = \beta' x_{qt} + \mu_q + \epsilon_{qt} \quad (1) $$

Where $y_{qt}$ is the log-normal of boarding and alighting, $x_{qt}$ is a column vector of attributes at station $q$ and time $t$, and $\beta$ is the corresponding coefficient column vector of parameters to be estimated. The random error term $\epsilon_{qt}$, is assumed to be an independently and identically distributed
normal error term for \( q \) and \( t \) with zero mean and variance \( \sigma^2 \), and \( \mu_q \) represent a spatial specific effect to account for all the station-specific time-invariant unobserved attributes. This spatial specific effect can be treated as fixed effects or random effects. In the fixed effects model, for every station a dummy variable is created while in the random effects model, \( \mu_q \) is treated as random term that is independently and identically distributed with zero mean and variance \( \sigma^2_\mu \). The spatial random effects and random error term are assumed to be independent. The fixed effects methodology is not appropriate in the presence of time-invariant independent variables. In addition, the fixed effects models estimate a large number of parameters (one parameter specific to each station); thus, are computationally cumbersome for large systems as ours. Therefore, in the current study, we restrict ourselves to a spatial random effects model\(^1\).

In traditional econometric literature, spatial dependency can be incorporated by employing different modeling frameworks, such as spatial lag or spatial autoregressive model (SAR), spatial error model (SEM), geographically weighted regression (GWR) and spatial durbin model. In the current study, we have considered two different forms spatial autocorrelations in examining bus ridership: 1) SAR model which accounts for spatial endogenous interactions by a spatially lagged dependent variable and 2) SEM model which accounts for spatial interactions by a spatial autocorrelation process in the error term. Specifically, the first model comprises endogenous interactions effects with dependent variable at other stops and in the second model the spatial interaction is captured through the error term.

A spatial lag model can be written as follows:

\[
y_{qt} = \delta \sum_{j=1}^{Q} w_{qj} y_{jt} + \beta' x_{qt} + \mu_q + \epsilon_{qt}
\]  

where \( \delta \) is called the spatial autoregressive coefficient and \( w_{qj} \) is an element from a spatial weight matrix \( W \). The diagonal elements of \( W \) matrix are zero and define the spatial arrangement of the stops. Again, in some literature, other types of spatial matrices are introduced. In our study, the spatial \( W \) matrix is a 3495×3495 matrix with elements equal to 1 for the stations that are within 800m buffer area of each other and zeros for the rest of the elements. It must be noted that diagonal of \( W \) matrix is set to be zero to prevent the use of \( y_{qt} \) to model itself. For stability in estimation, a row-normalized form of the \( W \) matrix is employed as our spatial weight matrix (see Elhorst, 2014) for more details on \( W \) matrix).

A spatial error model may be written as follows:

\[
y_{qt} = \beta' x_{qt} + \mu_q + \varphi_{qt}
\]  

---

\(^1\) We restrict ourselves to spatial random effects model as opposed to developing a spatial fixed effects model for multiple reasons. First, in a spatial fixed effects model several additional parameters are estimated to account for bus stop specific effects. In a dataset with over 3000 stops, this would mean estimating a large number of parameters. The presence of such large number of parameters might lead to over-fitting of the data. Second, in the presence of bus stop specific fixed effects, the impact of other variables that are common across the system are unlikely to be meaningful. Therefore, the results from such an exercise are not transferable to the future or other locations in any meaningful form. Hence, we have not considered spatial fixed effects models.
\[
\varphi_{qt} = \rho \sum_{j=1}^{Q} w_{qj} \varphi_{jt} + \epsilon_{qt}
\]

where \( \varphi_{qt} \) accounts for the spatial autocorrelated error term and \( \rho \) reflects the spatial autocorrelation coefficient. Both spatial lag model and spatial error model can be estimated using maximum likelihood approach (see Elhorst (2014) for details on likelihood functions). In this paper, we use Matlab routines provided by Elhorst (Elhorst, 2003; Elhorst, 2014), to estimate pooled spatial lag and error models with spatial specific random effects.

4. EMPIRICAL ANALYSIS
The Greater Orlando region with a population of 2.3 million in 2016 is a typical American city in the south with an automobile-oriented transportation system with the following mode shares: automobile (85.7%), Public transit (1.0%), walk (9.2%) and bike (1.2%). The main public transit service in the region is the Lynx system that serves an area of approximately 2,500 square miles within Orange, Seminole, Osceola and Polk County in Central Florida. The bus system operates 77 daily routes with average weekday ridership of around 105,000. The number of bus stops considered for the analysis includes 3,745 stops. Of these, 3,495 stops data are used for model estimation while 250 stops data are set aside for validation. In addition to Lynx, the transit system includes a newly launched commuter rail system – SunRail. The rail line is 31 mile long with 12 stations with average weekday ridership of about 3,800 in 2015. Figure 1 represents the study area along with the Lynx bus route, bus stops, SunRail line and SunRail station locations.

The ridership data was obtained from Lynx transit authority. For our analysis, weekday boarding and alighting data for the following 6 time periods are considered: May through August 2013, September through December 2013, January through April 2014, May through August 2014, September through December 2014, and January through April 2015. The final sample consists of 20,970 records (3,495 stations \( \times \) 6 quarters). The average daily stop level boarding (alighting) is around 21.03 (20.86) with a minimum of 0 (0) and maximum of 7,022 (6,770). The average daily ridership for January through April 2015 quarter is presented in Figure 2 (Figure 2(a) – Boarding and Figure 2(b) – Alighting). A summary of the system-level ridership (boarding and alighting) are provided in Table 1. The standard deviation is large as the ridership is different across different bus stops in our analysis.

In our study, we have conducted an extensive literature review and identified factors considered in public transit ridership field for identifying the universal set of attributes. GIS shape files from Lynx were used to generate the number of bus stops and bus route length. For creating the exogenous variables, we considered various buffer distances (800m, 600m, 400m, and 200m) from each bus stop. The exogenous variable information was generated based on multiple data sources including 2010 US census data, American Community Survey, Florida Geographic Data
Library, and Florida Department of Transportation databases. The exogenous attributes considered in our study can be divided into five broad categories: (1) Stop level attributes (such as headway), (2) Transportation and transit infrastructure variables (secondary highway length including major and minor arterials, and major collectors; rail road length and local road length, sidewalk length, Lynx bus route length, presence of shelter and distance of bus stop from CBD), (3) Built environment and land use attributes (such as land use mix, household density, employment density) (4) Sociodemographic and socioeconomic variables in the vicinity of the stop (income, vehicle ownership, age and gender distribution) and (5) Temporal and spatio-temporal lagged variables (such as stop boarding (alighting) in the last time period).

Temporal lagged variables were calculated for each bus stop by computing the boarding (alighting) variables from previous time period. Spatio-temporal lagged variables were created based on stops within the buffer (for various buffer sizes including 800m, 600m, 400m and 200m). The boarding (alighting) from previous time period for stops within the buffer were generated for spatio-temporal lag variables. The descriptive statistics of exogenous variables are presented in Table 2.

[Table 2 near here]

5. MODEL ESTIMATION RESULTS

5.1 Model Specification and Overall Measures of Fit

The empirical analysis in our study is based on two different models: 1) Spatial Error Model (SEM) and 2) Spatial Lag Model (SAR) for boarding and alighting ridership. The log linear independent models were estimated to serve as benchmark for advanced models. In this section, we compare SEM and SAR models. For each model type, the log-likelihood at convergence, R-square value, the number of parameters estimated, Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) were calculated (Burnham and Anderson, 2004). The AIC and BIC for a given empirical model are equal to:

\[
AIC = 2K - 2LL
\]

\[
BIC = -2LL + K \ln(Q)
\]

where \(LL\) is the log-likelihood value at convergence, \(K\) is the number of parameters, and \(Q\) is the number of observations. The model with the lower AIC or BIC is the preferred model. The log-likelihood values at convergence for the models estimated are as follows: (1) simple linear regression model for boarding (with 18 parameters) is -22,957.537, (2) simple linear regression model for alighting (with 18 parameters) is -22,911.193, (3) SEM for boarding (with 16 parameters) is -13,029.935, (4) SEM for alighting (with 15 parameters) is -12,361.319, (5) SAR for boarding (with 13 parameters) is -12,801.731 and (6) SAR for alighting (with 11 parameters) is -12,022.572. The BIC (AIC) values for the six models are as follows: (1) simple linear regression for boarding – 46,094.188 (45,951.073), (2) simple linear regression for alighting – 46,001.501 (45,858.386), (3) SEM for boarding is – 24,752.690 (26,091.870), (4) SEM for alighting is – 24,871.903 (26,219.084), (5) SAR for boarding is – 24,067.144 (25,629.462) and (6)
SAR for alighting is – 24,154.603 (25,732.823). Based on the information criteria, SAR model performs better for boarding and alighting. However, the number of explanatory variables are higher in SEM model. Hence, we consider both frameworks for our discussion. The results from the models for boarding and alighting are presented in Table 3.

5.2 Variable Effects
The final specification of the model development was based on removing the statistically insignificant (90% significance level) variables from the model. We considered various buffer size (800m, 600m, 400m and 200m buffer size) and considered the buffer size that offered the best data fit. Columns 2 through 5 present results from SEM and SAR models for boarding while columns 6 through 9 present results from SEM and SAR models for alighting. The model results are described by variable categories below.

Stop level Variables
The headway between buses at a stop has a significant influence on ridership. The result from all models confirms this. An increase in headway is associated with significant drop in ridership. The findings are in accordance with the previous literature (Abkowitz & Tozzi, 1986; Ding & Chien, 2001; I-Jy Chien, 2005; Kuah & Perl, 1988; Rahman et al., 2017; Ruan, 2009; Turnquist, 1981).

Transportation Infrastructures Variables
Several transportation infrastructure variables significantly affect boarding and alighting. Bus route length in a 600m buffer is associated with increase in boarding and alighting across all models. The result indicates that increase in the presence of bus route around the stop results in an increased adoption of public transit for the Greater Orlando region. This is an important finding highlighting how when adequate infrastructure for bus transit exists, it is likely to be used. Sidewalk length in an 800m buffer is observed to positively influence boarding and alighting in the SEM model. The corresponding coefficient was not significant in the SAR models. It is possible that the presence of sidewalk is serving as surrogate for walkable neighborhoods in the SEM model. The secondary highway length in a 600m buffer and local road length in an 800m buffer is positively associated with boarding for SEM and SAR models. However, these variables are statistically insignificant in the alighting models. Railroad length in an 800m buffer is negatively associated with alighting in only the SEM model. Finally, the presence of bus shelter at the bus stop is likely to positively influence boarding and alighting in SEM and SAR models.

Built Environment Variables
Several built environment variables are found to influence boarding and alighting. Land use mix variable is associated positively for boarding and alighting in SEM and SAR models. The result is quite encouraging toward promoting policies favoring mixed land use developments in urban regions. An increase in household density of census tract, where the bus stop is located, is negatively associated with alighting in SEM model. On the other hand, increasing employment density (of census tract) is negatively associated with boarding in SEM model. The distance of the stop from CBD variable impact follows an expected trend. Specifically, as the stop is away from CBD, the ridership is likely to reduce. The result confirms our expectation that large share of transit ridership occurs near the urban core.
**Sociodemographic and Socioeconomic Variables**
Several sociodemographic and socioeconomic variables based on census tract, where the bus stops are located, were found to significantly influence boarding and alighting. The proportion of people aged between 0 to 17 years is observed to positively influence boarding in both SEM and SAR models. The result is intuitive as an increase in the proportion of young individuals’ increases, population without access to car is also likely to increase. For alighting, the variable has a significant influence only in the SEM model. An increase in proportion of individuals 65 and higher is associated with a reduction in boarding and alighting (except for alighting in SAR model). The result while counter intuitive on first glance is representative of vehicle access among this age group. As the number of households in the high-income category increase, the model results indicate a possible reduction in boarding and alighting (except for boarding SAR model). The result is expected in a city like Orlando where high-income individuals are more likely to use their personal vehicle for travel. Finally, the number of households renting in a census tract is positively associated with boarding and alighting (except for boarding SAR model). The relationship between rent and ridership is along expected lines.

**Spatial and Spatio-temporal Effects**
The temporal lagged variables are positively associated with boarding and alighting ridership for SEM and SAR models. On the other hand, spatio-temporal lag variables present a reverse trend. To elaborate, the results indicate that stops with larger ridership in adjacent station for previous time period are likely to have a lower ridership. The result is indicative of competition from nearby stops. The result represents a system where the same ridership in the urban region is being split across stops.

**Spatial Error and Spatial Lag Effects**
The study estimated SEM and SAR models to account for the presence of spatial effects. The model fit measures clearly confirmed our hypothesis. In the SEM model, the results indicate the presence of a significant spatial autocorrelated error term. In the SAR model, the spatial autoregressive coefficient indicates a significant impact of unobserved effects.

**5.3 Model Validation**
A hold-out sample of 250 stops (250*6=1500 observation) was set aside for validation purposes. We used both SEM and SAR model to compute predicted boarding and alighting at the stop level. The predicted rates were compared with the observed boarding and alighting in the sample. We computed Mean Absolute Error (MAE) and Root Mean Square Error (RMSE) to compute the deviation from observed values. The MAE (RMSE) values for the four models are as follows: (1) boarding SEM – 0.815 (1.011), (2) boarding SAR – 0.837 (1.083), (3) alighting SEM – 0.809 (1.016), and (4) alighting SAR 0.897 (1.123). The results indicate a satisfactory performance for boarding and alighting models across the two systems. Overall, between the two model systems, the SEM models perform slightly better.

**6. CONCLUSION**
Toward encouraging higher level of public transport adoption, it is of utmost importance to examine the critical factors that contributes to public transport ridership. An important tool to evaluate the influence of the critical factors and the future public transit investments opportunities
is the application of statistical models. Drawing on stop level boarding and alighting data for 6 four-month periods for Greater Orlando region from May 2013 to April 2015, the current study estimated spatial panel models that accommodate for impact of spatial and temporal observed and unobserved factors.

Two spatial models: 1) Spatial Error Model (SEM) and 2) Spatial Lag Model (SAR) were estimated for boarding and alighting separately by employing several exogenous variables including stop level attributes, transportation and transit infrastructure variables, built environment and land use attributes, sociodemographic and socioeconomic variables in the vicinity of the stop and spatial and spatio-temporal lagged variables. The model fit measures clearly confirmed our hypothesis that spatial unobserved effects influence boarding and alighting through the presence of spatial auto-correlated error term in the SEM model and the spatial autoregressive coefficient in the SAR model. Further, the validation exercise results confirmed that the two model performed adequately. The outcomes of the estimated models can be employed to evaluate the changes in the public transport demand due to the changes in the future supply (adding or removing stops in the system). The optimal ridership could be predicted by employing the results of the estimated models while considering the spatial location of the proposed stops in relation to the existing bus stops (distance matrix). To be sure, the research is not without the limitations. In our model, we have considered both boarding and alighting model separately. The observed and unobserved factors for boarding and alighting ridership at the same stop can have an impact on ridership. Incorporating such station level dependency between boarding and alighting along with spatial unobserved factors is a potential avenue for future research. In the future, it would be beneficial to examine how individual level behavioral preferences for using private vehicle can be incorporated within transit ridership frameworks. There is also a need to accommodate for the endogeneity between transit agency decisions (with regards to headway and new bus routes) and ridership. In the current study, we have estimated SAR and SEM models which account for spatial endogenous interactions and spatial interactions in the error structures. In future, it might be interesting to estimate a spatial Durbin model which takes into account the advantage of both SAR and SEM models while also allowing for flexible spillover effects.

ACKNOWLEDGMENTS
The authors would like to acknowledge Mr. William Gant from Lynx and Mr. Jeremy Dilmore from Florida Department of Transportation (FDOT) for helping with data acquisition. The authors would also like to thank FDOT for funding this study. All opinions are only those of the authors. Authors would like to highlight that an earlier version of this paper was presented at the 2018 Transportation Research Board (TRB) Annual Meeting.
