ABSTRACT
Given the burgeoning growth in transport networking companies (TNC) based ride hailing systems and their growing adoption for trip making, it is important to develop modeling frameworks to understand TNC ride hailing demand flows at the system level. We identify two choice dimensions: (1) a demand component that estimates origin level TNC demand at the taxi zone level and (2) a distribution component that analyzes how these trips from an origin are distributed across the region. The origin level demand is analyzed using linear mixed models while flows from origin to multiple destinations is analyzed using a multiple discrete continuous model system (MDCEV). The data for our analysis is drawn from New York City Taxi & Limousine Commission (NYTLC) for twelve months from January through December 2018. For our analysis, we examine weekday morning peak hour demand and distribution patterns. The model components are developed using a comprehensive set of independent variables. The model estimation results offer very intuitive results for origin demand and distribution of flows across destinations. We validated the model by predicting trips to destination taxi zones and found that predicted model performs well in identifying high preference destination zones. In addition, elasticity effects are computed by evaluating the percentage change in baseline marginal utility in response to increasing the value of exogenous variables by 10%, 25% and 50% respectively.

Keywords: Ride hailing, Taxi zone level demand, Flow distributions, Linear mixed model, Multiple discrete continuous extreme value
BACKGROUND AND MOTIVATION

Ride hailing services have been available as a mode of transportation since the early 17th century in the form of horse-drawn hackney carriages in Europe. With the advent of the automobile, taxis for hire have been the most common ride hailing transportation alternative. However, ride hailing has undergone a rapid transformation in the recent few years in response to the transformative technological changes including smart mobile availability, ease of hailing a ride using mobile applications, integration of seamless payment systems and real-time driver and user reviews. In fact, the convenience offered by transport networking companies (TNC) such as Uber, Lyft, and Via has allowed for a tremendous growth in ride hailing demand. For example, in New York City, the average daily trips by taxi (yellow taxi) was varying between 400 thousand and 500 thousand for the years 2010 and 2014 (1). However, since 2014, with the advent TNC services in the city, the total number of trips have increased. Specifically in 2018, the daily trips have increased to more than a million trips with traditional taxi accounting for nearly 300 thousand trips, and TNC services accounting for 700 thousand trips. These trends are not specific to New York City. A recent report analyzing reimbursed travel in the US has found that the share of Uber and Lyft has increased from 8% to 72.5% within 2014-2018 at the cost of taxi and rental car business share (2). The prevalence of TNC services is also not restricted to US. Uber operates in over 60 countries, while Didi Express in China, Ola in India currently capture a large share of the ride hailing market in these countries. The immense growth in market share and the spread of these services across the world illustrate how the ride hailing market has undergone a rapid transformation in a short time frame.

The rapid transformation of the ride hailing market coupled with emerging shared mobility service expansions (such as Carshare, Bikeshare, and Scooter share) offers an unprecedented opportunity to address the existing mobility shortcomings in urban regions (as highlighted in a recent TCRP report (3). In fact, public transit and transportation planning agencies can enhance mobility and accessibility in a region by incorporating these shared transportation alternatives within their planning frameworks to provide holistic mobility options in denser urban regions. Specifically, dense urban regions with well-connected public transit systems can strategically target reducing the reliance on private automobile ownership (and use) by incorporating ride-hailing alternatives in trip planning tools. Further, by examining the spatio-temporal ride hailing data, transit agencies and shared mobility platforms can identify urban pockets with service needs to provide last mile connectivity. Towards understanding these patterns it would be beneficial to understand TNC demand and its spatial distribution in the region.

The current research effort contributes to this goal by developing quantitative models of TNC demand and flow distribution patterns. Using data from the NYC Taxi and Limousine commission, we conduct a comprehensive analysis of morning peak hour ride hailing data from Uber, Lyft, Juno and Via from 2018. The study develops (1) a demand component that estimates origin level TNC demand at the taxi zone level and (2) a distribution component that analyzes how these trips from an origin are distributed across the region. The former component is analyzed using linear mixed models and the latter component is analyzed using a multiple discrete continuous model system. The model components are developed using a comprehensive set of independent variables including aggregate trip attributes, transportation infrastructure variables, land use and built environment variables, weather attributes, and temporal attributes. The model estimates are validated using a hold out sample. Further, a policy exercise is conducted to illustrate how the proposed model system can be utilized for evaluating the impact of changes to independent variables.
EARLIER RESEARCH AND CURRENT STUDY

Ride hailing in its traditional form has received attention from various researchers (for example see (4) for detailed literature review of traditional taxi services). The research on TNC services is an emerging topic of interest in several fields including computer science, transportation, economics, and social sciences. In our analysis, we restrict ourselves to literature on TNC systems that are directly relevant from a transportation perspective.

Earlier research efforts focused on TNC ride hailing can be grouped into two streams. The first stream of studies explored TNC evolution, factors that affected usage, licensing and policy formulation, aggregate level interaction frameworks, pricing mechanisms, and comparison across ride hailing services (with taxis or between various smart phone based ride hailing companies). These studies typically rely on questionnaire interviews, and online surveys for data collection. TNC evolution studies focused on the definition of ride hailing systems, how ride hailing services have evolved over time (5-7), investigated the challenges and opportunities presented by real-time services and highlighted various opportunities for future (8; 9). Djavadian and Chow (10) developed an agent based framework to identify social optimum considering a pricing criterion within a two-sided market system. Zha et al. (11) conducted an aggregate economic analysis of ride-sourcing markets where customers and drivers are matched using an exogenous function. The authors provide guidance to regulators on the mechanisms to improve social welfare. A TCRP report (3) examining shared modes of travel (such as bikesharing, carsharing, and TNC systems) by conducting surveys and interviews across seven urban regions (Austin, Boston, Chicago, Los Angeles, San Francisco, Seattle, and Washington, DC). The study concluded that individuals who adopt shared modes for their travel needs are more open to public transit alternatives. Further, these shared modes can serve as complementary modes to public transit. A set of studies explored the influence of various factors affecting TNC usage. For example, Cramer and Krueger (12) analyzed passenger service times for Uber and taxi across five major cities in the US. The authors concluded that availability of driver-passenger reviews, Uber’s flexible labor supply model coupled with inefficient taxi regulations for passenger safety contributed to higher Uber utilization rates. Nie (13) also examined the competition between taxi industry and TNC and interestingly found that taxi industry in Shenzhen, China survived the emergence of ridesourcing. Rayle et al. (14) conducted a trip intercept survey to understand the source of TNC demand and concluded that nearly 50% of the demand is transferred from public transit and driving. Multiple studies explored pricing strategies employed by various ride hailing companies (15-17). Studies examining Uber surge pricing strategies, concluded that surge pricing has a negative impact on demand. Smart et al. (18) compared the performance of Uber and taxi services in terms of waiting time and cost using survey of riders in low income neighborhoods in Los Angeles. The data analysis found that Uber offered lower waiting times and provided service at a lower cost (even under surge pricing).

A second stream of studies conducted quantitative analysis using TNC usage data exploring trip patterns (a) to identify factors influencing TNC demand, (b) to understand TNC demand and its relationship with existing transportation modes. Earlier research has found that Uber demand is affected by temporal and weather patterns (19; 20). Other factors that were found to affect ride hailing demand include land use attributes such as lower transit access time (TAT), higher length of roadways, lower vehicle ownership, higher income and more job opportunities (21-23). Studies comparing the emerging ride hailing services with existing services such as public transit and bicycle sharing offer interesting results. Gerte et al. (24) found evidence for shifting taxi demand to smart phone based ride hailing services in New York City. Further, the study also found evidence of substitution relationship between ride hailing and bicycle share systems. Dey et al. (25) also studied the impact of various factors on shifting NYC’s TNC services demand from traditional (yellow and green) taxi services.
Komaduri et al. (26) analyzed data from RideAustin, to examine the trip length and temporal
distribution of the trips. A comparison of the adoption of RideAustin relative to public transit
alternatives illustrated that individuals were choosing RideAustin to minimize travel time
(highlighting the higher value of time for these travelers). Lavieri et al. (27) employed the same
data to develop a two stage framework for TNC demand analysis. The study employs averaged
daily TNC origin and distribution flows within a two step procedure. The model components
developed include a spatially lagged multivariate count model for TNC demand and fractional
split model for trip distribution. Poulsen et al. (28) examined how the two systems that were
introduced in the same time performed - Uber and Green taxis - in Manhattan area and found
that the growth rate for Uber was substantially higher. Babar and Burtch (29) compared the
utilization rate of transit service in the US after the introduction of TNC services and found
that utilization rate of bus service dropped while long-haul transit services (such as subway and
commuter rail) experienced increasing utilization. The spectrum of quantitative methodologies
employed in earlier studies include descriptive analysis, linear regression, logistic regression,
difference in difference model and panel based random effects multinominal logit model.

**Current Study in Context**
The review highlights the burgeoning literature on TNC services across the world. However,
given that TNCs are a very recent development several dimensions remain uninvestigated.
While TNC demand has been examined in earlier research, the temporal and spatial
aggregation employed in the past have not allowed for easy integration of these approaches
into existing planning frameworks. Further, earlier studies have rarely examined how the TNC
demand is distributed across the study region. Of the earlier research efforts Lavieri et al. (27)
developed a two stage framework for understanding TNC flow distribution. However, the
authors focused on an average model where the two dependent variables were averaged over
the study period to conduct the analysis. The averaging process, while simplifying the analysis
avoiding repeated measures of data, does not process the rich distributional differences across
the data and thus might not be suitable for prediction applications on a daily basis.

The primary objective of our research is to develop TNC demand based planning
models that can be integrated within existing frameworks or used to augment the outputs from
existing demand frameworks. With this primary objective, the current study makes the
following contributions. First, the current study develops a TNC demand model at the Taxi
zone level for the morning peak hour (represented as pickups in the data). The demand variable
is approximated as a continuous variable and a linear mixed model framework is employed to
analyze the data. Second, conditional on the origin taxi zone demand, we develop a distribution
model to determine TNC flows from the origin to all destinations in the study region. There
are two major challenges associated with modeling the TNC flow distribution. First, the
destinations for TNC flows from an origin are likely to involve multiple alternatives (as
opposed to a single chosen alternative). Second, the potential universal alternative set includes
all taxi zones in the system. The multiple discrete continuous approaches that follow Kuhn-
Tucker (KT) approaches developed in literature can be adapted to address this choice
dimension. In a recent study, Dey et al. (30) developed a similar framework for studying bicycle
sharing system flows. MDCEV framework employed in this study has several advantages over
the alternative approaches (such as fractional split model or the traditional trip based model).
First, the MDCEV model allows us to capture for satiation effects – i.e. as more trips are
destined to a zone, there is a drop in the value gained for subsequent trips. The accommodation
for such zones can account for potential challenges with high demand to a zone such as
unavailability of TNC services. Second, the fractional split model allocates a proportion to an
alternative as a function of exogenous variables. Given the functional form, it is theoretically
possible that some probability is allocated to each alternative (however small). However, in the
presence of a large number of alternatives – as is the case in our context – the proportion
allocated to these potentially unchosen alternatives could amount to be a significant value.
Thus, it might be necessary to adopt a two-step model where a binary model determines
whether a zone is chosen or not and then for these chosen alternatives, a proportion is assigned.
The reader would note that destination preferences can also be modeled employing a
disaggregate trip level model (such as Faghih-Imani and Eluru (31) for bikeshare). However,
in the absence of any individual specific characteristics an aggregate model reduces the data
burden while offering similar insights.

The data for our analysis from January 2018 through December 2018 is drawn from
NYC Taxi & Limousine Commission (NYTLC). The data provides taxi zonal level daily origin
demand and the corresponding flow patterns from the origin to all destinations across the
system. The two model components were developed using a host of independent variables
including trip attribute, transportation infrastructure variables, land use and built environment
variables, weather attributes, and temporal attributes. The model estimation results for the
proposed model offers intuitive results. The proposed model was also validated using a hold-
out sample and prediction exercise is undertaken.

DATA

New York City with high residential density and large tourist population is an ideal market for
ride hailing systems. The NYC Taxi and Limousine Commission (TLC) provides spatially
aggregated trip data from all ride hailing companies (taxi, Uber, Lyft, Juno and Via) for public
use (https://www1.nyc.gov/site/tlc/about/tlc-trip-record-data.page). The trip itinerary dataset
for 2018 for Uber, Lyft, Juno and Via was processed to obtain daily morning peak hour TNC
usage patterns. The dataset provides information on start and end time of trips, origin and
destination defined as taxi zone ID, trip distance and vehicle license number. The trip data was
augmented with other sources including: (1) built environment attributes derived from New
York City open data (https://nycopendata.socrata.com); (2) socio-demographic characteristics
at the census tract/zip code level gathered from US 2010 census data; (3) the weather
information corresponding to the Central Park station retrieved from the National Climatic
Data Center (http://www.ncdc.noaa.gov/data-access).

Sample Formation

A series of data cleaning and compilation exercises were undertaken for generating the sample
data for estimation purposes. First, trips with missing or inconsistent information were
removed. Second, trips longer than 500 minutes in duration (around 0.5% of all trips) were
deleted considering that these trips are not typical ride-sharing trips. These trips could also be
a result of two possibilities; either destination of those trips could be outside NYC or due to
technical issues the trip information was recorded incorrectly. Third, trips that had the origin
and destination outside of NYC taxi zone were also eliminated. Therefore, we focus on trips
that originated and were destined within NYC taxi zone region only.

For the given study period (January 2018 to December 2018), the total number of
available taxi zones in NYC was 260. Initially, we aggregated morning peak (6.30 am-9.30am)
trip data for each day for each week (total 52 weeks) from each origin taxi zone ID to every
possible destination taxi zone ID (260). The average number of daily trips generated and
attracted at each taxi zone is presented in Figure 1. In Figure 1, the number of trips generated
(Figure 1a) and attracted (Figure 1b) to each taxi zone is categorized into multiple classes from
very low to very high. The figures clearly highlight the high TNC usage in Manhattan and
airport locations (LaGuardia, John F. Kennedy International Airport and Newark airport).
For our analysis, to ensure that holiday weekends that are likely to have a different user patterns do not influence our analysis, we selected morning peak period trip data for 43 weeks without any holidays. The processing of the large sample of trip data is substantially time-consuming and significantly increases the model run times. To obtain a reasonable sample size for model estimation, we sampled following two steps; 1) 150 taxi zones were selected randomly from the total 260 taxi zones and 2) for each taxi zone one weekday was randomly selected for each week.

Thus, the data sampled had 150 taxi zone with 43 weekday morning peak trip data during 2018. While the data considered is a sample, the consideration of a reasonably large sample size (6450) allows for robust model estimations. We organized the dataset into two components for our analysis; 1) For zonal level origin demand (aggregating total daily morning peak trip at the origin level) and 2) Trip distribution from origin to destination (aggregating daily morning peak trip at the O-D pair level).

**Independent Variable Generation**

Several independent variables were generated in our study (see Table 1). These can be grouped into five categories: 1) Trip attribute, 2) Transportation infrastructure variables, 3) Land use and built environment variables, 4) Weather attributes, and 5) Temporal attribute.

**Trip attribute** includes the network distance between each origin-destination taxi zone pair estimated using the shortest path algorithm tool of ArcGIS software. While the actual trip might involve a different route, the shortest network distance would be an appropriate indicator of the distance traveled. The variable will serve as a surrogate for travel time. As all the data is for morning peak, the impact of congestion is likely to be affecting all records similarly.

**Transportation infrastructure attributes** created at the taxi zone level include bike route length density (capturing the effect of availability of bicycle facilities on system usage), number of bikeshare stations, length of streets (minor and major streets). Number of subway stations and bus stops in the taxi zone were generated to examine the influence of public transit on rider’s preference of destination station.

Several **land use and built environment variables** were considered including population density, job density and establishment density, the number of institutional facilities (schools, colleges, hospitals), the number of point of interests (museums, shopping malls), and the number of restaurants (including coffee shops and bars), total area of parks and commercial space (office, industry, retail) within each taxi zones. Distance of destination from Times Square and airport were estimated by using the shortest path algorithm tool of ArcGIS software. Airport indicator variable for the taxi zone was generated to examine the additional impact of airport destination. Population, job density and median income information was collected from US Census for 2014-2017 and extrapolated for 2018 at the census tract level considering average yearly population change from 2014-2017. Household car ownership information for 2018 was used to generate proportion of zero car ownership at taxi zone level to examine the impact of car ownership on riders’ destination preferences. Non-motorized vehicle score (average of walk score and bike score) and transit score associated with each taxi zone was considered at the census tract level. Further, crime density and accident density were also generated at taxi zone level. Total number of crimes of all types for previous year (2017) was aggregated at census tract level and crime density was estimated by dividing with the corresponding year’s population. In a similar manner, total number of accidents of all kind for each day of 2018 was considered to generate accident density.

**Weather variables** include average temperature, precipitation, and snow for that particular day. Several interaction variables were also created. Seasonality is the only **temporal variable** considered. We consider winter (December-February), Spring (March-May), Summer (June-August) and Fall (September-November) as dummy variables.
Descriptive Analysis
The data at an aggregate system level in the form of average number of trips by taxi zone for each week is presented in Figure 2. The various weeks with lower demand correspond to the weeks with holidays supporting our hypothesis that these weeks have a different demand pattern. The dependent variable distribution is generated to understand origin level demand and distribution of these flows across the study region. On average, 384 trips depart from each origin taxi zone in the morning peak hour and are destined to about 67 alternative taxi zones. The sample characteristics of the independent variables generated are presented in Table 1.

ECONOMETRIC FRAMEWORK

Linear Mixed Model for Station Level Weekly Origin Demand
The taxi zonal level daily pick up demand variable is a continuous value and can be analyzed using linear regression models. However, the traditional linear regression model is not appropriate for data with multiple repeated observations. In our empirical analysis, we observe the daily peak hour demand at the same taxi zone for fourty-three weeks. Hence, we employ a linear mixed modeling approach that builds on the linear regression model while incorporating the influence of repeated observations for the same station. The linear mixed model collapses to a simple linear regression model in the absence of any station specific effects.

Let \( w = 1, 2, ..., W \) be an index to represent each taxi zone \((W = 150)\), \( M = 1, 2, ..., 43 \) be an index to represent the various day of weeks of data compiled for each pick up taxi zone. The dependent variable (daily peak hour demand) is modeled using a linear regression equation which, in its most general form, has the following structure:

\[
y_{mw} = \beta X_{mw} + \varepsilon_{mw}
\]  

(1)

where \( y_{mw} \) is the natural logarithm of weekly demand, \( X \) is an \( K \times 1 \) column vector of attributes and the model coefficients, \( \beta \), is an \( K \times 1 \) column vector. The random error term, \( \varepsilon_{mw} \), is assumed to be normally distributed across the dataset. In our analysis, the repetitions over days can result in common unobserved factors affecting the dependent variable. While a full covariance matrix can be estimated for the unobserved correlations, as we are selecting 43 random days from a sample of 43 weeks for each taxi zone, we decided to employ a simpler covariance structure. The exact functional form of the covariance structure assumed is shown below:

\[
\Omega = \begin{pmatrix}
\Omega^2 + \Omega_1^2 & \Omega_1 & \ldots & \Omega_1 \\
\Omega_1 & \Omega^2 + \Omega_1^2 & \ldots & \Omega_1 \\
\vdots & \vdots & \ddots & \vdots \\
\Omega_1 & \Omega_1 & \ldots & \Omega^2 + \Omega_1^2
\end{pmatrix}
\]

(2)

The covariance structure restricts the covariance across all fourty-three records to be the same. The parameters estimated in this correlation structure are \( \Omega \) and \( \Omega_1 \). The parameter \( \Omega \) represents the error variance of \( \varepsilon \). \( \Omega_1 \) represents the common correlation factor across daily records. The models are estimated in SPSS using the Restricted Maximum Likelihood Approach (REML). The REML approach estimates the parameters by computing the likelihood function on a transformed dataset. The approach is commonly used for linear mixed models (32).

MDCEV Model for Destination Choice
According to Bhat et al. (33), we consider the following functional form for utility in this paper, based on a generalized variant of the translated Constant Elasticity of Substitution (CES) utility function:
\[ U(x) = \sum_{i=1}^{l} \frac{\gamma}{\alpha} \lambda_i \left\{ \left( \frac{x_i}{\gamma} + 1 \right)^{\alpha} - 1 \right\} \]  

(3)

where \( U(x) \) is a quasi-concave, increasing, and continuously differentiable function with respect to the consumption quantity \((lx1)\)-vector \((x_i \geq 0 \text{ for all } i)\), and \( \lambda_i \) associated with drop off taxi zone \( i \). \( \lambda \) represents the baseline marginal utility \((\lambda_i > 0 \text{ for all } i)\), \( \gamma \) is a translation parameter \((\gamma \text{ should be greater than zero})\) which enables corner solutions while simultaneously influencing satiation and \( \alpha \) influences satiation \((\alpha \leq 1)\).

The KT approach employs a direct stochastic specification by assuming the utility function \( U(x) \) to be random over the population. A multiplicative random element is introduced to the baseline marginal utility for each good (in our case destination) as follows:

\[ \lambda(y_{iw}, \rho_{iw}) = \exp(\delta y_{iw} + \rho_{iw}) \]  

(4)

where \( y_{iwq} \) is a set of attributes characterizing drop off taxi zone \( i \) during day \( w \), \( \delta \) corresponds to a column vector of coefficients, and \( \rho_{iw} \) captures idiosyncratic (unobserved) characteristics that impact the baseline utility for destination stations. The overall random utility function of Equation (3) then takes the following form:

\[ U(x) = \sum_{i=1}^{l} \frac{\gamma}{\alpha} \exp(\delta y_{iw} + \rho_{iw}) \left\{ \left( \frac{x_i}{\gamma} + 1 \right)^{\alpha} - 1 \right\} \]  

(5)

Following (34; 35), consider a generalized extreme value distribution for \( \rho_i \) and assume that \( \rho_{iw} \) is independent of \( y_{iw} \) \((i = 1, 2, \ldots, l)\). The \( \rho_{iw} \)'s are also assumed to be independently distributed across alternatives with a scale parameter normalized to 1. Due to the common role of \( \gamma \) and \( \alpha \), it is very challenging to identify both \( \gamma \) and \( \alpha \) in empirical application (see (35) for detailed discussion). Hence, either \( \gamma \) or \( \alpha \) parameter is estimated. When the \( \alpha \)-profile is used, the utility simplifies to:

\[ U(x) = \sum_{i=1}^{l} \frac{1}{\alpha} \exp(\delta y_i + \rho_i) \{ (x_i + 1)^{\alpha} - 1 \} \]  

(6)

When the \( \gamma \)-profile is used, the utility simplifies to:

\[ U(x) = \sum_{i=1}^{l} \gamma \exp(\delta y_i + \rho_i) \ln \left( \frac{x_i}{\gamma} + 1 \right) \]  

(7)

In this study, \( \gamma \)-profile is used. Finally, the probability that an pick up taxi zone has flows to the first \( D \) drop-off taxi zones \( D \geq 1 \) is:

\[ P(e_1^*, e_2^*, e_3^*, \ldots, e_D^*, 0, 0, \ldots, 0) = \left[ \sum_{n=1}^{D} d_n \right] \left[ \sum_{n=1}^{D} d_n \right] \frac{1}{\left( \prod_{n=1}^{D} e_{un} \right)^{\alpha}} (D - 1)! \]  

(8)

where \( \left( \sum_{n=1}^{D} m_n \right) \left( \frac{1}{\sum_{n=1}^{D} 1/m_n} \right) \) is defined as Jacobian form for the case of equal unit prices across goods (35) where, \( m_n = \left( \frac{1-\alpha}{\alpha} \right) \).
Unlike the traditional MDCEV model, in our context, the number of alternatives is substantially larger. Hence, we resort to estimating a generic parameter for each exogenous variable across alternatives (analogous to how multinomial logit based location choice models are estimated with a single utility equation).

**ESTIMATION RESULTS**

The model estimation results from the two models are discussed – TNC demand model followed by the trip distribution model results. The reader would note that variable selection was guided by earlier research on emerging modes of transportation such as bikeshare and TNC. From the universal set of variables we tested, variables that were significant at 95% confidence interval and offered intuitive results were included in the models.

**Trip Demand Model**

**Model Fit Measures**

A linear regression model was estimated at first as benchmark for evaluating the linear mixed model. To compare these two models, a Log-likelihood ratio (LR) test was computed. The LR value was found to be 1915 which was higher than any corresponding chi-square value for 2 degrees of freedom. Based on the LR test statistic, we can conclude that the linear mixed model outperforms the simple linear regression model and offers satisfactory fit for the station level demand.

**Linear Mixed Model Results**

The linear mixed model estimation results for morning peak hour TNC origin demand are presented in Table 2. The model estimation results offer intuitive findings. TNC demand, as expected is positively associated with population density. Increased median income of households within the taxi zones is found to increase demand for TNC trips (see (18; 22) for similar results). The presence of airport in the taxi zone also contributes to increased TNC demand. Higher number of trips are likely to be generated from taxi zones with higher population than lower populated zones. The presence of different institutional facilities (such as schools, colleges, hospitals, and office) in the taxi zones increases the zonal demand. The presence of discretionary opportunities such as a higher presence of restaurants and sidewalk café also drives TNC demand. Taxi zones with higher proportion of residential area is positively associated with Peak hour morning TNC flows. The result illustrates the adoption of TNC service for morning commute activities from these zones. The results for precipitation variables highlight that in the presence of precipitation individuals are likely to make a trip via TNC services (see (19) for similar result). The results also indicate a positive influence of summer and fall season compared to winter and spring season. The finding is in line with earlier research (19). The result is also possibly reflecting the increased tourist activity during these seasons.

**Correlation Parameters**

In the linear mixed model, we estimate a parameter that recognizes the repeated measures of data for each taxi zone. The correlation parameter is statistically significant highlighting the role of common unobserved factors influencing the demand from taxi zones.
TNC Distribution Model

Model Fit Measures
The final log-likelihood values for the estimated MDCEV model and equal probability MDCEV model are -1531122.801 and -1712633.216 respectively. The log-likelihood ratio (LR) test-statistic of comparison between the final model and the equal probability model is 363020.830. The LR test-statistic value is significantly higher than the corresponding chi-square value for 22 additional degrees of freedom highlighting that the MDCEV distribution model offers a reasonable fit.

MDCEV Model Results
The model results of TNC morning peak hour distribution model are presented in Table 3. The presentation of results is organized by the various variable categories. The reader would note that a single utility equation is estimated for all the destination zones (analogous to location choice model estimation for large number of alternatives). A positive (negative) coefficient indicates an increase (decrease) in the variable results in increasing the utility of the alternative destination.

Land Use and Built Environment Attributes
Zones located in census tracts with higher population density are more likely to be chosen as destination locations. Similarly, job density also impacts destination preference positively. The results together point towards the adoption of TNC services for daily commute trips (see Correa et al. (22) for similar result). Taxi zones with high income are preferred destination zones for TNC services. The model parameter for taxi zone level zero car household proportion highlights the increased adoption of TNC services among these zones (Correa et al. (22) found similar association with lower vehicle ownership households).

As expected, increased transit accessibility within a taxi zone increases the likelihood of the zone being chosen as a destination. On the other hand, the results indicate that zones with higher non-motorized score are less preferred destinations. While the result seems counterintuitive, it might be alluding to potential competition between TNC ride hailing and bicycle sharing systems in these zones. The presence of activity opportunities in the forms of restaurants and cafes, institutional facilities, and recreational centers and point of interests (POI) are positively associated with the destination zone preference. Taxi zone with higher commercial area serves as an attraction for TNC demand. The increase in land use mix value (range between 0 and 1) has a positive impact on destination zone preference.

The presence of airport in the destination taxi zone, as expected, increases the preference for the zone. The model also considers the influence of another major landmark in the region - Times Square. The parameter indicates that as the taxi zone is further from Times Square the preference of the zone as a destination reduces. The result illustrates how Times Square and its proximal zones serve as attraction centers for regular and tourist travel.

Trip Attributes
In the current research context, a negative coefficient was obtained for network distance of O-D pair. With the increasing distance to the destination, TNC demand distribution propensity reduces.

Transportation Infrastructure and Attributes
Several transportation infrastructure variables were considered in the demand distribution models. Of these variables, bike lane density, bikeshare stations, street length, bus stops and subway stations presented significant impacts on destination preferences. Taxi zones with
higher bike length density (defined as ratio of bike length to overall roadway length) reduce
the preference for the destination zone. The negative association with number of bikeshare
stations within a taxi zone highlights that TNC demand is likely to be lower for a destination
zone with more bikeshare stations. It is possible that the result alludes to potential competition
between these modes for the last mile connectivity. It would be interesting to explore these
differences further in future studies. An increase in the street length within the destination zones
results in an increased likelihood of the zone being chosen as destination (similar to findings
of Correa et al. (22)). As the number of bus stops and subway stations in the taxi zone increases,
we observe increased preference for that destination. The coefficient actually indicates a
potential complementarity between TNC flows and transit flows. TNC users might use public
transit for large portions of their trip and then use TNC for their final travel to the destination.

Temporal and Weather Attributes
The reader would note that temporal and weather attributes cannot be considered directly in
destination distribution model. Hence, we interacted these variables with destination specific
variables such as network distance and distance to Times Square. The results offer interesting
results. In Winter, the negative influence of network distance increases further indicating that
shorter trips are preferred (relative to other months). The temperature variable interacted with
network distance indicates that the influence of network distance is moderated by higher
temperature i.e. as temperature increases the negative impact of network distance reduces. The
precipitation variable interacted with network distance and distance to Times Square highlights
the increase in sensitivity to travel time under precipitation conditions. The weather variables
as a whole highlight how TNC distance impact is lower in good weather relative to poor
weather.

Satiation Parameter
We used distance to Times Square from taxi zones as a satiation parameter. In MDCEV model,
the satiation parameter captures the extent of decrease in marginal utility across different
destination zones. The satiation parameter is statistically significant at 95% confidence level,
thereby implying that there are clear satiation effects in destination choice as distance of
destination from Times Square increases. To elaborate, as the zone is further away from Times
Square, the satiation impacts are higher indicating fewer trips will be made to the zone.

VALIDATION ANALYSIS RESULTS
For validation purpose, a hold-out sample was prepared following the same procedure used to
extract the estimation sample. After extracting 150 taxi zones for our base dataset, the
remaining 110 taxi pick up zones were set aside for validation. Then we randomly chose 43
days from 43 corresponding weeks throughout the year for these 110 zones. The same approach
of data preparation employed for estimation sample is exercised for validation sample (110
origins x 43 days x 260 destinations). Using the validation data, the model results from the
estimation sample were used to generate a prediction measure in the form of predictive log-
likelihood. The difference in the log-likelihood for the predicted and equal probability model
is 3626720.830 units clearly highlighting the enhanced fit of the proposed model.

To further highlight the applicability of estimated model for predicting destination
choice conditional on the origin, we estimated destined trips from each origin for each day at
disaggregate level. Note that, zero trips to any destination for a week was also considered. To
identify the preferred destination zones, top 10 percentile of preferred destination zones was
captured for each pickup zone and validated with the top 10 percentile predicted destination
zones. For the performance evaluation, we compute the correctly classified predicted trips for
top 10 percentile destined zones for each taxi zone considering the total trips throughout the
year. The reader would note that about 71% of the top destination zones were correctly classified. To provide a visual representation, we selected 5 random taxi zones from 5 NYC boroughs and predicted the top 10 percentile destination zones for them considering average daily morning peak hour trips throughout the year and compared them with observed top destination zones for that particular zone (See Figure 3). Across the five boroughs, based on the observed and predicted measures from the Figure, taxi zones situated in Brooklyn offered the best prediction performance while taxi zone from Staten Island has inferior prediction performance. Overall, the two validation exercises, highlight the applicability of the proposed approach for TNC demand and distribution prediction.

POLICY ILLUSTRATION

The model results from Table 3 provide an indication of how the exogenous variables affect the network flows considering destination choice. However, they cannot provide the exact magnitude of the effect of these exogenous variables. Hence, elasticity effects computation considering changes of baseline marginal utility was used to evaluate the impact of exogenous variables on destination choice. The elasticity effects are computed by evaluating the percentage change in marginal utility of an alternative in response to increasing the value of exogenous variables from best fit model by 10%, 25% and 50% respectively. We selected five independent variables for presentation including job density, median income, network distance, institutional facilities and bus stops and subway stations. The computed elasticities are presented in Figure 4. Based on elasticity effects results in Figure 4, following observations can be made. First, the elasticity estimate for job density variable indicates that about 6.5, 17 and 37% increase in utility happens due to 10, 25 and 50% change in the independent variable. All the other results can be interpreted similarly. Second, rank order of the top three significant variable in terms of changes for the utility without considering positive or negative impact include network distance, job density and median income. Third, network distance between O-D can be considered as a proxy for travel time. The increasing value of this variable provides a snapshot of the impact of additional travel time due to traffic congestion or other safety incidents. Overall, the elasticity analysis results provide an illustration on how the proposed model can be applied to determine the critical factors contributing to increase in utility to choose a taxi zone as destination.

CONCLUSIONS

Given the burgeoning growth in ride hailing systems and their growing adoption for trip making, it is important to develop modeling frameworks to understand ride hailing demand flows at the zonal level. The current research effort contributes to this goal by developing quantitative models of TNC demand and flow distribution patterns. We identify two choice dimensions: (1) a demand component that estimates origin level TNC demand at the taxi zone level and (2) a distribution component that analyzes how these trips from an origin are distributed across the region. The origin level demand is analyzed using linear mixed models while flows from origin to multiple destinations is analyzed using a multiple discrete continuous model system (MDCEV).

The data for our analysis is drawn from New York City Taxi & Limousine Commission (NYTLC) for twelve months from January through December 2018. For our analysis, we examine weekday morning peak hour demand and distribution patterns. The model components are developed using comprehensive set of independent variables including aggregate trip attributes, transportation infrastructure variables, land use and built environment variables, weather attributes, and temporal attributes. The model estimation results provide intuitive findings for both zonal level demand and flow distribution behavior. The model estimates are validated using a holdout sample set aside. The data fit relative to the equal
probability MDCEV model highlighted the significant improvement in data fit for the estimated model. Several prediction exercises were also conducted to illustrate the value of the proposed model framework including identifying the top 10 percentile destinations and elasticity effect of changes to independent variables. The policy analysis results offer intuitive results and provide a mechanism for transportation planners to evaluate the impact of various changes on TNC demand and distribution.

The framework developed can be employed by planning agencies to evaluate how TNC originate in the region and their distribution. The model framework can be employed to evaluate how TNC flows in the future evolve as a function of various attributes. The future TNC flow prediction can be used to explore TNC flow inequity and potential mobility impacts of transportation infrastructure. The reader would note that while estimating the distribution component model (MDCEV) might be involved for practitioners, its application for prediction is not as involved and is relatively easier with tools available in open source platforms such as R.

This paper is not without limitations. Given the large number of alternatives, the model run times were substantially long affecting number of specifications we can test. In this context, another potential avenue for future research is the consideration of sampling for MDCEV models (similar to sampling in MNL models). It might also be interesting to evaluate the proposed approach with the approach proposed in Lavieri et al. (27), and/or the traditional trip distribution approaches. Empirically, several improvements can be considered in future research. It would be useful to examine the bikeshare flows between various zones and their impact on TNC flows. The model developed might also benefit from the consideration of transit connectivity between taxi zones in the region.

AUTHOR CONTRIBUTION STATEMENT
The authors confirm contribution to the paper as follows: study conception and design: Naveen Eluru, Bibhas Kumar Dey; data collection: Bibhas Kumar Dey; model estimation and validation: Bibhas Kumar Dey; analysis and interpretation of results: Bibhas Kumar Dey, Sudipta Dey Tirtha, Naveen Eluru; draft manuscript preparation: Bibhas Kumar Dey, Sudipta Dey Tirtha, Naveen Eluru. All authors reviewed the results and approved the final version of the manuscript.
